Scheuermann's Kyphosis

Scheuermann's disease (also called *Scheuermann's kyphosis*) is a condition that starts in childhood. It affects less than one percent of the population and occurs mostly in children by the age of 11. It affects boys and girls equally. Those who do not get proper treatment for the condition during childhood often experience back pain from the spinal deformity as adults

In Scheuermann's disease, the front of the vertebral body becomes wedge-shaped, possibly from abnormal growth. This produces a triangular-shaped vertebral body, with the narrow, wedged part closest to the front of the body. The wedge puts a bigger bend in the kyphosis of the thoracic spine.

The vertebral bodies are separated by a cushion, called an *intervertebral disc*. Between each disc and vertebral body is a *vertebral end plate*. Sometimes one or more discs in patients with Scheuermann's disease squeeze through the vertebral end plate, which is often weaker in patients with Scheuermann's disease. This forms pockets of disc material inside the vertebral body, a condition called *Schmorl's nodes*. A long ligament called the *anterior longitudinal ligament* connects on the front of the vertebral bodies. This ligament typically thickens in patients with Scheuermann's disease. This adds to the forward pull on the spine, producing more wedging and kyphosis.

The disease usually produces kyphosis in the middle section of the *thorax* (the chest), between the shoulder blades. The condition sometimes causes kyphosis in the lower part of the thoracic spine, near the bottom of the rib cage.

Why do I have this problem?

Famed for discovering this disease, Scheuermann himself thought a lack of blood to the cartilage around the vertebral body caused the wedging. Though scientists have since disproved this theory, the root cause of the disease is still unknown.

Mounting evidence suggests wedging develops as a problem vertebral body grows. During normal growth, the cartilage around the vertebral body turns evenly and completely to bone. If the change from cartilage to bone doesn't

happen evenly, one side of the vertebral body grows at a faster rate. By the time the entire vertebral body turns to bone, one side is taller than the other. This is the wedge shape that leads to abnormal kyphosis. Other theories of how Scheuermann's kyphosis starts include:

Genetics - Researchers have suggested that this disease can be passed down in families.

Childhood osteoporosis - One medical study found that some patients with Scheuermann's disease had mild *osteoporosis* (decreased bone mass) even though they were very young. Other studies did not show problems with osteoporosis. More research is needed to confirm the role of osteoporosis in Scheuermann's disease.

Mechanical Reasons - These include strains from bending, heavy lifting, and using poor posture. This theory makes sense because the back braces used in treating kyphosis work. If a back brace can straighten a bent spine, then perhaps mechanical forces could cause more kyphosis than naturally occurs in the spine. (Back braces are discussed in more detail later.) Scientists are not convinced that mechanical reasons cause the disease; rather, these factors likely aggravate the condition.

What are the symptoms?

Hunched posture in children usually alerts parents or teachers to the need for a doctor visit. Children don't typically complain of back pain or other symptoms. This is not the case in adolescents who are nearing puberty and have kyphosis in the lowest part of the thorax, near the bottom of the rib cage. In these patients, back pain is the overriding problem. This happens most often to young, active males. Doctors suspect this unique form of the disease occurs because the condition is overlooked during childhood, delaying treatment.

Adults who've lived with the hunched posture for many years may note worsening pain. The pain typically causes them to seek medical help. Patients of all ages who experience pain generally report feeling discomfort along the sides of the spine, slightly below the main part of the abnormal curve. In rare cases, the spinal cord is affected. A severe kyphosis stretches the spinal cord over the top of the curve. This can injure the spinal cord.

Also, patients with Scheuermann's disease have a greater chance of having a *herniated thoracic disc*. This is where the disc material from inside the disc begins to squeeze out and press on the spinal cord. Spinal cord symptoms for both situations include sensations of pins and needles and numbness. The leg muscles may feel weak. Symptoms from an injured spinal cord can also include changes in bowel and bladder function.

Exaggerated kyphosis can lead to an *increased lordosis* (inward curve) in the low back. This puts extra strain on the tissues of the low back. Over many years, this added wear and tear may produce low back pain. This mainly occurs in adults who have extra lumbar lordosis from years of untreated Scheuermann's disease. When the kyphosis angle exceeds 100 degrees, the sharply bent spine puts pressure on the heart, lungs, and intestines. When this occurs, patients may tire quickly, suffer shortness of breath, feel chest pain, and lose their appetite.

How do you diagnose Scheuermann's disease?

I start with a complete history and physical examination. However, X-rays are the main way to diagnose Scheuermann's kyphosis.

Taken from the side, an X-ray may show vertebral wedging, Schmorl's nodes, and changes in the vertebral end plates. I use X-ray images to measure the angle of kyphosis. We diagnose Scheuermann's disease when three vertebrae in a row wedge five degrees or more and when the kyphosis angle is greater

than 45 degrees. A side-view X-ray can also show if the spine is flexible or rigid. Patients are asked to bend back and hold the position while an X-ray is taken. The spine straightens easily when it is flexible. In patients with Scheuermann's disease, however, the curve stays rigid and does not improve by trying to straighten up. From the front, X-rays show if the spine curves from side to side. This sideways curve is called *scoliosis* and occurs in about one-third of patients with Scheuermann's kyphosis.

X-rays can show signs of wear and tear in adults who have extra lumbar lordosis from years of untreated Scheuermann's disease.

Magnetic resonance imaging (MRI) uses magnetic waves rather than X-rays to show the soft tissues of the body. This machine creates pictures that look like slices of the area the doctor is interested in. The test does not require special dye or a needle.

Computed tomography (a CT scan) may be ordered. This is a detailed X-ray that lets doctors see slices of the body's tissue. *Myelography* is a special kind of X-ray test. For this test, dye is injected into the space around the spinal canal. The dye shows up on an X-ray. This test is especially helpful if the doctor is concerned whether the spinal cord is being affected. These tests are rarely needed.

What treatment options are available?

A child or youth with mild kyphosis may simply need to be observed. Unless the curve or pain becomes worse, no other treatment may be needed. Some children who don't require treatment eventually improve and have no long-term problems. Others may always have a mild thoracic kyphosis but are able to function normally without pain or other problems.

If I am concerned that the curve will worsen, I may suggest bracing and exercise. A brace is most effective when used before the skeleton matures at about age 14. Doctors commonly choose a *Milwaukee brace*, which is designed to hold the shoulders back and gradually straighten the thoracic curve. The brace won't reverse the curve in a fully developed spine. Nor is it helpful for rigid curves that angle more than 75 degrees. The Milwaukee brace is made of molded plastic that conforms to the waist. On the back, two upright, padded bars line up along the sides of the spine. Pressure from the upright bars straightens the spine. Patients usually remove the brace to shower, but they keep it on at night. Younger patients (under 15) generally wear the brace all the time. We adjust the brace regularly as the curve improves. When the thoracic curve has improved enough, the brace is worn part-time (eight to 12 hours per day) until the skeleton is done growing, typically around age 14 or 15.

A physical therapist may show the patient recommended exercises. When used in combination with a brace, exercises appear to maximize the effect of

the brace by strengthening muscles that help align the spine. Certain exercises, such as general conditioning and stretching, are also worthwhile for helping patients control pain. However, exercises alone don't reduce kyphosis in Scheuermann's disease. Certain exercises are beneficial when used in combination with a brace. Upper back exercises, such as gentle back bends (*extension*) can improve posture and prevent the spine from slouching forward. Hamstring stretches and pelvis exercises improve posture by preventing extra lordosis in the low back. Aerobic exercise improves heart and lung health and combats pain.

Pain is also addressed by the physical therapist. The therapist may apply heat, cold, ultrasound, and massage treatments. Adults who've had kyphosis for many years (and the resulting low back pain from too much lordosis) benefit from postural exercises to reduce the lumbar curve, followed by stabilization exercises to help them keep better posture. Patients benefit most when these exercises are done regularly and for a lifetime.

I may prescribe anti-inflammatory medication for pain. Younger patients generally use this medicine on a short-term basis, in combination with other treatments. Adults who have ongoing pain sometimes require long-term use of anti-inflammatory medication.

When is surgery needed?

We rarely recommend surgery for Scheuermann's disease. Certain situations may require it, however. For example, surgery may be needed if pain becomes severe and doesn't go away with non-operative treatment. Patients whose skeletons are done growing may require surgery. Patients with a rigid kyphosis that angles more than 75 degrees may also need surgery. Two procedures commonly used to treat thoracic kyphosis are:

Posterior fusion with instrumentation - In a fusion operation, two or more bones are joined into one solid bone. We perform *posterior fusion* for Scheuermann's disease on the rare patient who prefers not to use a brace and whose spine is still growing, is mildly flexible, and has a kyphosis of less than 65 degrees. This surgery is done through the back (*posterior*) of the spine. After making an incision in the back, the surgeon applies pressure to straighten the kyphosis. Small strips of bone graft are then laid over the back of the spinal column. These strips encourage the bones to grow together. Metal rods are attached

along the spine to prevent the vertebrae from moving. The rods hold the spine in better alignment and protect the bone graft so it can heal better and faster.

Combined fusion - *Combined fusion* is actually two fusion surgeries, one from the back (posterior) and one from the front (*anterior*) of the spine. In the past, two separate operations were needed, but now some surgeons do both fusions in the same operation. This surgery is commonly used if the spine is finished growing and the kyphosis angle is more than 75 degrees. We start with anterior fusion.

With the patient on his or her side, the thoracic surgeon cuts away a piece of rib to make a small opening on the side of the thorax. The rib opening is spread apart so the surgeon can reach the spine better. The spine surgeon operates on the front of the spine through the chest cavity. A section of the anterior longitudinal ligament is cut. This makes it easier to straighten the hunched spine. The intervertebral discs in the problem area are taken out, and the spaces between the wedged vertebrae are filled with bone graft. I grind up the piece of rib that was removed and place it in the disc spaces. This is the method I use most commonly. As the grafts heal, the vertebrae become fused into solid bone. The second part of surgery is an involved form of posterior fusion using special rods and screws. This part of the operation can be done right after the anterior fusion or scheduled for one week later. First, the surgeon makes an incision over the back of the spine. The skin and muscles are spread apart. Occasionally, we must cut the bone (called osteotomy) at one or more levels to help correct the kyphotic deformity. Then strips of bone graft are laid across each vertebra to be fused. Long rods are inserted along the sides of the spine. The rods are attached to the bones with screws. Adjusting the shape of the rods allows us to correct the shape of the spine to a more normal position. The rods help hold the spine steady as the bone grafts heal. The rods are usually left in permanently.
